Now, if you recall in compression ignition engines are diesel engines 1 of the main components of the engine exhaust was also the soot particles, why because diesel is basically has a higher molecular weight and when it dissociates you know some of the carbon in the high molecular compound may remain unoxidized it can essentially remain in the form of carbon, which then joined together and power form these particulates, the soot particles.

(Refer Slide Time: 00:53)

So, if one wants to remove them the solution is to use what are called particulate traps. So, as we discussed in the previous lecture particularly even if you look at a heavy vehicle a truck or a bus, when it starts accelerating from rest or from slow speed it goes to start moving. So, we can see that you know to give the treatment system is not proper or the entire system is not working properly we would see this black smoke coming out of the tailpipe those are particulates. So obviously very harmful so the question is how we address them.

So, particulate traps are used to remove particulates in the exhaust of CI engines so, that is the main role. So, they are nothing but filters that are in the form of a ceramic mat or a metal wire mesh. So that is a particulate trap. So, what happens is like these particulate traps are installed in the exhaust and when the exhaust gases with the small particulates come through they get caught in the caught in these measures. So, the particulates can be removed from the exhaust before there before the exhaust gases reach that atmosphere.

But what is the flip side of this process as the particulates start getting collected in this mesh, they are going to block the flow of exhaust and that is going to increase the engine back pressure which will then potentially affect the engine operating conditions and performance. So, we need to ensure that these traps are periodically cleared of the particulate matters. So, that is a challenge for the operation of these particulate filters.

So, as the particulates accumulate the trap particulates restrict the exhaust flow process and thus increasing the back pressure. So, what does typically require is that the strands need what is called as regeneration. So, this term regeneration in this context is used to refer to the process by which the particulates are oxidized. So, this means that you know like we need to subject the particulate filter itself to high temperatures to and provided enough oxygen to oxidize this carbon soot particles.

(Refer Slide Time: 05:07)

The screenshot shows a Windows Journal window with the following handwritten notes:

- Thus, these traps need "regeneration", that is, the process by which the particulates are oxidized.
- Modern CI engines with advanced injection technology and well-designed combustion chambers have greatly reduced particulates in emissions.

Exhaust Gas Recirculation [EGR]:

- Reducing peak cylinder temperature  $\Rightarrow$  lower  $\text{NO}_x$ , but lower  $\eta_m$ .
- Dilute the fresh fuel-air mixture with a non-reacting gas.
- Exhaust gases are added to the fresh fuel-air mixture in EGR.
- Limitations - reduces engine efficiency, increase HC emissions.
- EGR  $\rightarrow$  not used under Wide Open Throttle (when maximum power is desired) and at idling / low speeds (when there is already significant dilution by exhaust gases).

A small video inset in the bottom left corner shows a man in a blue shirt speaking. The bottom right corner of the journal window features the NPTEL logo and the text 'NPTEL'.

So, there is a process of regeneration and that is going to be a very, not a very ideal scenario. But that is a limitation of using a particular filter but in modern diesel engines if you look at modern CI engines, one uses advanced injection technology and well-designed combustion chambers in order to promote proper combustion. So the amount of particulates in the engine exhaust by design of proper injection and combustion chamber has been greatly reduced in modern diesel engines.

So in modern CI engines with advanced engine technology and well-designed combustion chambers greatly reduce the particulate filter concentration so that is one feature of modern CI. So that is as far as particular traps are concerned you know like that are addressed to reduce the content of soot in the engine exhaust. So the next technique which is used to reduce  $\text{NO}_x$  in engine exhaust is what is called as exhaust gas recirculation EGR.

So what does this exhaust gas recirculation? So exhaust gas recirculation typically a process by which the amount of NO<sub>x</sub> is reduced by mixing the exhaust gases with the fresh fuel air mixture burnt in the cylinder why would anyone want to do that you know that at first glance you know, why would we want to mix burn gases with fresh fuel air mixture that is going to reduce the combustion efficiency is a none. However, mixing the burn fuel exhaust gases with the fresh fuel air mixture particularly will reduce the peak cylinder temperatures during conversion.

And if we recall, NO<sub>x</sub> formation is the highest when the cylinder temperatures are the highest and it takes place very near to the stoichiometric fuel air ratio with a slightly leaner mixture. So that like we have enough oxygen for oxidation of nitrogen. So, under such conditions adding these exhaust gases would be beneficial although it is a tradeoff now at the expense of reducing NO<sub>x</sub> we are slightly going to reduce the engine performance. So, that is a tradeoff which we have to leave it.

So, what do we what is the idea behind this you know like reducing peak cylinder temperature implies lower NO<sub>x</sub> but reduce thermal efficiency also that is the flip side of reducing the peak cylinder temperature? So, how can we do this we can dilute the fresh fuel air mixture with a non-reacting gas and in the engine, you know like the exhaust gases fit this requirement. So exhaust gases are added to the fresh fuel air mixture in easier so typically they are taken from the exhaust system and added somewhere in the inlet section inlet manifold of the engine.

So, exhaust gases are direct to the fresh fuel mixture in this process of exhaust gases gas recirculation. So, as we have already discussed one main limitation is that it reduces the engine efficiency. Another limitation if not properly done it can also significantly increase hydrocarbon emission because in the fresh fuel air mixture at the expense of not increasing the cylinder temperature to a high extent if he had too much exhaust gases what may happen is that the unburned hydrocarbons in the fresh fuel our mixture themselves will not combust in the first place.

Because we need for proper condition we need hydrocarbons we need oxygen and a mechanism for initiating combustion. So, if we diluted the fresh fuel air mixture it is too much of exhaust

that may potentially prevent proper combustion of the incoming fresh fuel air mixture. So, it may potentially increase hydrocarbon emissions. And typically, due to this reason, and also based on points that we have already discussed, easier is typically not used, when we want a rich fuel air mixture.

What are the conditions under which we want a rich fuel air mixture the first one is during idling, because during idling anyway the fresh fuel air mixture is diluted by exhaust gases, you know, like why would anyone want to add more exhaust gases to the fresh fuel air mixture. And then like, what is called is wide open throttle. That is like when we press the throttle towards its full maximum portion where we want the maximum power. Even that we want a rich mixture to get more energy from the engine.

So we would not want to essentially add more exhaust gases to reduce itself. So easier is typically not used under what is called as wide open throttle then maximum power is desired and idling low speeds under these conditions when there is already significant dilution by exhaust gases so, that is the process of exhaust gas recirculation. So, the main purpose is to reduce NOx by bringing down the peak cylinder temperatures.

(Refer Slide Time: 13:12)

The screenshot shows a Windows Journal window with the title bar 'EDS160\_Journal\_Engines - Windows Journal'. The journal contains handwritten notes in purple ink. The first section is titled 'Selective Catalytic Reduction [SCR]:' and lists four bullet points: 'Decrease NO<sub>x</sub> content in exhaust by reducing NO<sub>x</sub> to N<sub>2</sub>.', 'The reductant is usually automotive grade urea [Diesel Exhaust Fluid (DEF)], which is an aqueous mixture of 32.5% urea and 67.5% deionized water.', 'Vanadia and zeolite-based catalysts are typically used.', and 'A main requirement is the need for replenishing DEF periodically.' The second section is titled 'Other Emissions' and has an arrow pointing to a sub-point 'i) Evaporative Losses → HC emission in fuel tank, carburetor.' followed by a bullet point: 'Evaporative Loss Control Systems → a charcoal canister is used to store the fuel vapours from the fuel tank and then purge the vapours back to the engine.' The bottom of the window shows a small video feed of a man in a blue shirt and the Windows taskbar with the time 11:50 AM.

Selective Catalytic Reduction [SCR]:

- Decrease NO<sub>x</sub> content in exhaust by reducing NO<sub>x</sub> to N<sub>2</sub>.
- The reductant is usually automotive grade urea [Diesel Exhaust Fluid (DEF)], which is an aqueous mixture of 32.5% urea and 67.5% deionized water.
- Vanadia and zeolite-based catalysts are typically used.
- A main requirement is the need for replenishing DEF periodically.

Other Emissions →

- i) Evaporative Losses → HC emission in fuel tank, carburetor.
- Evaporative Loss Control Systems → a charcoal canister is used to store the fuel vapours from the fuel tank and then purge the vapours back to the engine.

Another way of reducing NOx in our neck which is also like applied in particularly heavy vacanze is what is called as selective catalytic reduction. So, what is this so, these are various tools you know like available to reduce the engine emissions, so, selective catalytic reduction

abbreviated as SCR, so, selective catalytic reduction is also used to decrease NO<sub>x</sub> content in exhaust by reducing NO<sub>x</sub> to N<sub>2</sub> in this process, the reductant which is a chemical that is used in the in this process is usually automotive grade urea.

So what is this automotive grade urea, so it is also commonly called as diesel exhaust fluid so abbreviated as DEF which is typically an aqueous mixture of around 32.5% urea and 67.5% deionized water so that is what is called as the automotive grade urea or diesel exhaust fluid so there is the reductant which reacts with NO<sub>x</sub> and then like, reduces to N<sub>2</sub>. So to enable this process typically catalysts are used, which are Vanadia and Zeolite based catalyst are typically used to accelerate this reduction reaction, so that is selective catalytic reduction.

So this pretty efficient in reducing the NO<sub>x</sub> levels by up to 90%. But of course, a main requirement is that one needs to replenish the supply of this DEF there is automotive grade urea that is a separate time for that it gets spent as we treat NO<sub>x</sub>, so we need to replenish that supply. So the main requirement is, the need for filling or replenishing the periodically. So that is selective catalytic reduction. So these are the main tools that are available now for treating engine exhaust.

So, the last topic I want to briefly touch upon as far as emissions and that control is concerned other emissions typically you know like involved evaporative losses. So, whatever we have looked at till now or what are called as tailpipe emissions or engine exhaust emissions. So, they come from the engine exhaust systems and only what are other emissions there are other emissions in an engine predominantly from evaporative losses you know to take the form of hydrocarbon emissions in fuel tank and carburetor if a carburetor is present.

So, what happens in a fuel tank is that like as the temperature of the fuel tank increases, fuel vaporizes, and what happens is that like if the fuel tank is vented to the atmosphere as the vapor pressure increases in the fuel tank, the mixture of vaporize fuel and air escape through the vent due to increasing temperature and corresponding increase in pressure they went escape to the atmosphere when the fuel tank cools down as an atmosphere will enter into enter through the vent in the fuel tank, but anyway we are lost the fuel air.

So this evaporative hydrocarbon loss takes place in the fuel tank. So, now how do we address this? So, in fact, evaporative losses and fuel tanks are more when the fuel tank is partially filled so that like we have more space for vaporization and the escape of fuel and air vapors. So, of course, the level of the fuel in the fuel tank varies with operation so it is really difficult for us to maintain fully full tank all the time is not it so today you know like people use you know, like what are called as evaporative loss control systems.

Were typically a charcoal canister is used to absorb, the fuel vapors from the fuel tank and then purge the vapors back to the engine when required, so that is the evaporative loss control system which is used to address.

(Refer Slide Time: 20:09)

which is an aqueous mixture of 32.5% urea and 67.5% deionized water].

- Vanadia and zeolite-based catalysts are typically used.
- A main requirement is the need for replenishing DEF periodically.

Other Emissions

- i) Evaporative Losses → HC emission in fuel tank, carburetor.
- Evaporative Loss Control Systems → a charcoal canister is used to store the fuel vapours from the fuel tank and then purge the vapours back to the engine.
- ii) Crankcase Blowby: Leakage of fuel past the piston rings into the crankcase.

This vaporization in the fuel air another case of this unburn hydrocarbon emissions is what is called as crankcase blow by where in the fuel vapors escape through the crevices around the piston rings in the cylinder and due to the high pressures that exists in the cylinder and on the escape to the piston rings, oil rings creases and into the crankcase and of course, this becomes more as the engine becomes older because these crevices become bigger with variant.

So this is nothing but leakage of fuel pasty piston rings into the crankcase that is what it is called crankcase, so these are the other emissions that can occur in engine crankcase globally obviously increases engine edge as barren tine occurs. So this completes discussion of emissions and is to

regulate engine emissions because that is very important today in the current context, because emission standards are becoming tougher and tougher to essentially protect our environment.

So our system just a broad discussion to understand what these are and how do we address them at least in concept. So with this, I stop, conclude our discussion on engines. So from the next lecture, we will start looking at the transmission. So how the energy is going to be transmitted from the engine to the wheels and we will start the discussion in the next lecture. Thank you.
